

A global analysis of inclusive diffractive cross sections at HERA

C. Royon ^{*}, L. Schoeffel[†], S. Sapeta [‡], R. Peschanski [§], E. Sauvan ^{**}

We describe the most recent data on the diffractive structure functions from the H1 and ZEUS Collaborations at HERA using four models. First, a Pomeron Structure Function (PSF) model, in which the Pomeron is considered as an object with parton distribution functions. Then, the Bartels Ellis Kowalski Wüsthoff (BEKW) approach is discussed, assuming the simplest perturbative description of the Pomeron using a two-gluon ladder. A third approach, the Bialas Peschanski (BP) model, based on the dipole formalism is then described. Finally, we discuss the Golec-Biernat-Wüsthoff (GBW) saturation model which takes into account saturation effects. The best description of all available measurements can be achieved with either the PSF based model or the BEKW approach. In particular, the BEKW prediction allows to include the highest β measurements, which are dominated by higher twists effects and provide an efficient and compact parametrisation of the diffractive cross section. The two other models also give a good description of cross section measurements at small x with a small number of parameters. The comparison of all predictions allows us to identify interesting differences in the behaviour of the effective pomeron intercept and in the shape of the longitudinal component of the diffractive structure functions. In this last part, we present some features that can be discriminated by new experimental measurements, completing the HERA program.

I. INTRODUCTION

After many years, new measurements of the diffractive structure function have been made at the ep collider HERA, where 27.5 GeV electrons or positrons collide with 820 or 920 GeV protons [1–4]. The purpose of this paper is to analyse all these data under three different theoretical approaches, which are described in section II. We also study the compatibility of all experimental data, by fitting all sets together for each model. In this introduction, we remind briefly the main features of the models, used in this paper to understand the diffractive interactions.

In a frame where the incident proton is very fast, the diffractive reaction can be seen as the deep inelastic scattering (DIS) of a virtual photon on the proton target, with a very fast proton in the final state. We can therefore expect to probe partons in a very specific way, under the exchange of a color singlet state. Starting with the pioneering theoretical work of Ref. [5], the idea of a point-like structure of the Pomeron exchange opens the way to the determination of its parton (quark and gluon) distributions, where the Pomeron point-like structure can be treated in a similar way as (and compared to) the proton one. Indeed, leading twist contributions to the proton diffractive structure functions can be defined by factorisation properties [6] in much the same way as for the full proton structure functions themselves. As such, they should obey DGLAP evolution equations [7], and therefore allow for perturbative predictions of their Q^2 evolution. On a phenomenological ground, these Diffractive Parton Distribution Functions (DPDFs) are the basis of MC simulations like RAPGAP [8] and they give a comparison basis with hard diffraction at the Tevatron [9], where the factorisation properties are not expected to be valid. Moreover, the study of DPDFs is also a challenge for the discussion of different approaches and models where other than leading twist contributions can be present in hard diffraction. Indeed, a strong presumptive evidence exists that higher twist effects may be quite important in diffractive processes contrary to non-diffractive ones which do not require (at least at not too small Q^2) such contributions. In fact, there are models which incorporate non-negligible contributions from higher twist components, especially for relatively small masses of the diffractive system. One of our goals in this paper is to take into account this peculiarity of diffractive processes.

It is also useful to look at ep scattering in a frame where the virtual photon moves very fast (for instance in the proton rest frame, where the γ^* has a momentum of up to about 50 TeV at HERA). The virtual photon can fluctuate into a quark-antiquark pair, forming a small color dipole. Because of its large Lorentz boost, this virtual pair has a lifetime much longer than a typical strong interaction time. Since the interaction between the pair and the proton is

mediated by the strong interaction, diffractive events are possible. An advantage of studying diffraction in ep collisions is that, for sufficiently large photon virtuality Q^2 , the typical transverse dimensions of the dipole are small compared to the size of a hadron. The interaction between the quark and the antiquark, as well as the interaction of the pair with the proton, can be treated perturbatively. With decreasing Q^2 the color dipole becomes larger, and at very low Q^2 these interactions become so strong that a description in terms of quarks and gluons is no longer justified, and the diffractive reactions become very similar to those in hadron-hadron scattering.

The outline of the paper is as follows. In section II, we introduce the different models used to fit the HERA data that are described in section III. In section IV we start the analysis of these data with the PSF based approach, leading to the concept of parton distribution functions. We extract DPDFs under several fit conditions and many details are discussed in appendix A and B. Then, in sections V to VII, we follow with fits of HERA data using dipole models, for which we can consider saturation effects. In particular, the case of the two-gluon exchange model (BEKW) is shown to be quite efficient to reproduce the data over a large kinematic range including the higher-twist part. Results are discussed in section VIII. All the approaches covered in this paper give different properties concerning, e.g., the Pomeron intercept dependences and the longitudinal diffractive structure function. These aspects are discussed and an outlook is given.

II. MODELS

In this section, we discuss the phenomenology of the different models used to fit the HERA data.

A. Pomeron Structure Function (PSF) model

1. Reggeon and Pomeron contributions

The diffractive structure function $F_2^{D(3)}$ is investigated in the framework of Regge phenomenology and expressed as a sum of two factorized contributions corresponding to a Pomeron and secondary Reggeon trajectories [9]:

$$F_2^{D(3)}(Q^2, \beta, x_P) = f_{\mathbb{P}/p}(x_P) F_2^{D(\mathbb{P})}(Q^2, \beta) + f_{\mathbb{R}/p}(x_P) F_2^{D(\mathbb{R})}(Q^2, \beta), \quad (1)$$

where x_P is the fractional momentum loss of the incident proton and β has the form of a Bjorken variable defined with respect to the momentum $P - P'$ lost by the initial proton as illustrated on Fig. 1¹.

FIG. 1. Schematic diagram of inclusive diffractive DIS, $ep \rightarrow eXp$. Four-momenta are indicated in parentheses.

¹In a partonic interpretation, β is the momentum fraction of the struck quark with respect to the exchanged momentum $P - P'$ (the allowed kinematical range of β is between 0 and 1).

In the parametrisation defined by Eq. (1), $F_2^{D(P)}$ can be interpreted as the Pomeron structure function and $F_2^{D(R)}$ as an effective Reggeon structure function, with the restriction that it takes into account various secondary Regge contributions which can hardly be separated. The Pomeron and Reggeon fluxes are assumed to follow a Regge behaviour with linear trajectories $\alpha_{P,R}(t) = \alpha_{P,R}(0) + \alpha'_{P,R}t$, such that

$$f_{P/p,R/p}(x_P) = \int_{t_{cut}}^{t_{min}} \frac{e^{B_{P,R}t}}{x_P^{2\alpha_{P,R}(t)-1}} dt, \quad (2)$$

where $|t_{min}|$ is the minimum kinematically allowed value of $|t|$ and $t_{cut} = -1 \text{ GeV}^2$ is the limit of the measurement. The values of the t -slopes parameters can be taken from Ref. [1]: $\alpha'_P = 0.06 \text{ GeV}^{-2}$, $\alpha'_R = 0.30 \text{ GeV}^{-2}$, $B_P = 5.5 \text{ GeV}^{-2}$ and $B_R = 1.6 \text{ GeV}^{-2}$. Following the procedure described in Ref. [9], the Pomeron intercept $\alpha_P(0)$ is let as a free parameter in the QCD fit and $\alpha_R(0)$ is fixed to 0.50.

The apparent Regge-factorisation breaking, in other words, the fact that we can not separate the x_P from the β and Q^2 dependence of the diffractive structure function is explained in these kinds of models by introducing the Pomeron and Reggeon trajectories. As we see in the following, other models such as dipole models show an intrinsic factorisation breaking and it is of great interest to see if the secondary trajectories are still needed by the fits.

2. Extraction of parton densities in the Pomeron

We assign parton distribution functions to the Pomeron and to the Reggeon. A simple prescription is adopted in which the parton distributions of both the Pomeron and the Reggeon are parametrised in terms of non-perturbative input distributions at some low scale Q_0^2 . For the structure of the sub-leading Reggeon trajectory, the pion structure function [11] is assumed with a free global normalization to be determined by the data.

For the Pomeron, a quark flavour singlet distribution ($zS(z, Q^2) = u + \bar{u} + d + \bar{d} + s + \bar{s}$) and a gluon distribution ($zG(z, Q^2)$) are parametrised at an initial scale Q_0^2 , such that

$$zS(z, Q^2 = Q_0^2) = [A_S z^{B_S} (1-z)^{C_S} (1 + D_S z + E_S \sqrt{z})] \cdot e^{\frac{0.01}{z-1}}, \quad (3)$$

$$zG(z, Q^2 = Q_0^2) = [A_G (1-z)^{C_G}] \cdot e^{\frac{0.01}{z-1}}, \quad (4)$$

where $z = x_{i/P}$ is the fractional momentum of the Pomeron carried by the struck parton. In the following, we present the results in terms of quark density with the hypothesis that $u = \bar{u} = d = \bar{d} = s = \bar{s}$, which means that any light quark density is equal to $zS/6$.

Concerning the QCD fit technology, we fix $\alpha_S(M_Z^2) = 0.118$ and the functions zS and zG of Eq. (3) and (4) are evolved to higher Q^2 using the next-to-leading order DGLAP evolution equations with the code of Ref. [12]. All fits have also been performed with the code of Ref. [13] as a cross check which leads to the same results within 2%. The contribution to $F_2^{D(P)}(\beta, Q^2)$ from charm quarks is calculated in the fixed flavour scheme using the photon-gluon fusion prescription given in Ref. [14]. The contribution from heavier quarks is neglected. No momentum sum rule is imposed because of the theoretical uncertainty in specifying the normalization of the Pomeron or Reggeon fluxes and because it is not clear that such a sum rule is appropriate for the parton distributions of a virtual exchange.

Note that diffractive distributions are process-independent functions. They appear not only in inclusive diffraction but also in other processes where diffractive hard-scattering factorisation holds. The cross section of such a process can be evaluated as the convolution of the relevant parton-level cross section with the DPDFs. For instance, the cross section for charm production in diffractive DIS can be calculated at leading order in α_s from the $\gamma^* g \rightarrow c\bar{c}$ cross section and the diffractive gluon distribution. An analogous statement holds for jet production in diffractive DIS. Both processes have been analysed at next-to-leading order in α_s . A natural question to ask is whether the DPDFs extracted at HERA can be used to describe hard diffractive processes like the production of jets, heavy quarks or weak gauge bosons in $p\bar{p}$ collisions at the Tevatron. The fraction of diffractive dijet events at CDF is a factor 3 to 10 smaller than would be expected on the basis of the HERA data. The same type of discrepancy is consistently observed in all hard diffractive processes in $p\bar{p}$ events, see e.g. [15]. In general, while at HERA hard diffraction contributes a fraction of order 10% to the total cross section, it contributes only to about 1% at the Tevatron. This QCD-factorisation breaking observed in hadron-hadron scattering can be interpreted as a survival gap probability or a soft color interaction that need to be considered in such reactions, and a detailed computation of DPDFs from HERA can help in a better understanding of this phenomenon.

B. The Bartels Ellis Kowalski Wusthoff (BEKW) model

This model assumes the simplest perturbative description of the Pomeron by a two-gluon ladder [16]. Contrary to the QCD fits described in the previous section, there is no concept of DPDFs in this approach. In Ref. [16], a parametrisation of the diffractive structure function in terms of three main contributions is proposed. The first term describes the diffractive production of a $q\bar{q}$ pair from a transversely polarised photon, the second one the production of a diffractive $q\bar{q}g$ system, and the third one the production of a $q\bar{q}$ component from a longitudinally polarised photon. We note that the higher Fock states such as $q\bar{q}gg$ are not included in this model as we discuss it further in the next section. More explicitly, we consider the modified form of the two-gluon exchange model, as expressed in Ref. [3], and labeled BEKW fits.

The three different contributions read

$$F_2^{D(3)}(q\bar{q}_T) = A \left(\frac{x_0}{x_{\mathbb{P}}} \right)^{n_2} \beta(1-\beta) , \quad (5)$$

$$F_2^{D(3)}(q\bar{q}g_T) = B \left(\frac{x_0}{x_{\mathbb{P}}} \right)^{n_2} \alpha_S \left(\ln \left[\frac{Q^2}{Q_0^2} + 1 \right] \right) (1-\beta)^\gamma , \quad (6)$$

$$F_2^{D(3)}(q\bar{q}_L) = C \left(\frac{x_0}{x_{\mathbb{P}}} \right)^{n_4} \left(\frac{Q_0^2}{Q^2 + Q_0^2} \right) \left(\ln \left[\frac{Q^2}{4Q_0^2\beta} + 7/4 \right] \right)^2 \beta^3(1-2\beta)^2 , \quad (7)$$

where

$$n_{2(4)} = n_{2(4)}^0 + n_{2(4)}^1 \ln \left[\frac{Q^2}{Q_0^2} + 1 \right] . \quad (8)$$

The ansatz for the β -dependence is motivated by general features of QCD-parton model calculations: at small β (large diffractive masses M_X) the spin 1/2 (quark) exchange in the $q\bar{q}$ production leads to a behavior $\sim \beta$, whereas the spin 1 (gluon) exchange in the $q\bar{q}g$ term corresponds to β^0 . For large β (small diffractive masses) perturbative QCD leads to $1-\beta$ and $(1-\beta)^0$ for the transverse and longitudinal $q\bar{q}$ terms respectively. For the $q\bar{q}g$ term in $q\bar{q}g$ the situation is slightly more complicated : the exponent γ is left as a free parameter. Concerning the Q^2 dependence, the first two terms are leading twist whereas the last one belongs to higher twist. The $\ln Q^2$ -terms follow from QCD-calculations, and they indicate the beginning of the QCD Q^2 -evolution. Finally, the dependence on $x_{\mathbb{P}}$ cannot be obtained from perturbative QCD and therefore is left free. An additional sub-leading trajectory [11] is added to the model, as for the DGLAP based fit, using the pion structure function to describe the Reggeon exchange.

The free parameters in the fit are the three normalisation factors A , B and C , the n_2^0 , n_4^0 , n_2^1 factors which describe the $x_{\mathbb{P}}$ dependence of the cross section and are not predicted by QCD, and the γ parameter which describes the β dependence of the $q\bar{q}g$ term. In the above parametrisation, n_4^1 is set to zero, x_0 is fixed to 0.1, Q_0^2 is taken to be 1 GeV² and α_S is taken at the fixed value of 0.25. The sub-leading trajectory [11] is added to the model, with an overall normalisation $n_{\mathbb{R}}$ as a further free parameter, the flux definition being the same as in section II A 1.

C. The Bialas Peschanski (BP) model

The dipole model [19] provides another approach to describe the Pomeron as a perturbative object where high Fock states are introduced ($q\bar{q}gg$, $q\bar{q}ggg$...). In this approach, two components contribute to the diffractive structure function [21]. First, an elastic component corresponds to the elastic interaction of two dipole configurations. It is expected to be dominant in the finite β region, for small relative masses of the diffractive system. Secondly, there is an inelastic component where the initial photon dipole configuration is diffractively dissociated in multi-dipole states by the target. This process is expected to be important at small β (large masses).

A sub-leading trajectory [11] is added to the model, with an overall normalisation $n_{\mathbb{R}}$ as a further free parameter, the flux definition being the same as in in section II A 1. The different contributions read

$$F_2^{D(3)} = N^{in} F_2^{D(3),inel} + N_T^{el} F_T^{D(3),qel} + N_L^{el} F_L^{D(3),qel} + N_{\mathbb{R}} F_2^{D(3),Reggeon} \quad (9)$$

The transverse and longitudinal elastic components can be written as

$$F_T^{D(el)} = 12 \frac{N_c e^2 \alpha_s^4}{\pi} x_{\mathbb{P}}^{-2\alpha_{\mathbb{P}}+1} a^3(x_{\mathbb{P}}) \log^3 \frac{Q}{2Q_0\sqrt{\beta}} e^{-a(x_{\mathbb{P}}) \log^2 \frac{Q}{2Q_0\sqrt{\beta}}} \quad (10)$$

$$\times \beta(1-\beta) \left[{}_2F_1 \left(-\frac{1}{2}, \frac{3}{2}; 2; 1-\beta \right) \right]^2 , \quad (11)$$

$$F_L^{D(el)} = 16 \frac{N_c e^2 \alpha_s^4}{\pi} x_{\mathbb{P}}^{-2\alpha_{\mathbb{P}}+1} a^3(x_{\mathbb{P}}) \log^2 \frac{Q}{2Q_0 \sqrt{\beta}} e^{-a(x_{\mathbb{P}}) \log^2 \frac{Q}{2Q_0 \sqrt{\beta}}} \quad (12)$$

$$\times \beta^2 \left[{}_2F_1 \left(-\frac{1}{2}, \frac{3}{2}; 1; 1 - \beta \right) \right]^2, \quad (13)$$

with

$$\alpha_{\mathbb{P}} = 1 + \Delta_{\mathbb{P}} \left(\frac{1}{2} \right) = 1 + \frac{\alpha_s N_c}{\pi} 4 \log 2, \quad (14)$$

and

$$a(x_{\mathbb{P}}) = \frac{\pi}{7\zeta(3)} \alpha_s N_c \log \frac{1}{x}. \quad (15)$$

The inelastic component is given by

$$F_{T,L}^{D(in)} = 2^9 \sqrt{\frac{2}{\pi}} H_{T,L} \left(\frac{1}{2} \right) \frac{N_c e^2 \alpha_s^5}{\pi^4} x_{\mathbb{P}}^{-2\alpha_{\mathbb{P}}+1} a^3(x_{\mathbb{P}}) \frac{Q}{Q_0} e^{-\frac{a(\beta)}{2} \log^2 \frac{Q}{4Q_0}} a^{\frac{1}{2}}(\beta) \beta^{-\Delta_{\mathbb{P}}}. \quad (16)$$

The free parameters used in the fit are $\alpha_{\mathbb{P}}(0)$, the exponents for the Pomeron and the secondary reggeon, the normalisations in front of the inelastic N^{in} , transverse elastic N_T^{el} , longitudinal elastic N_L^{el} and the Reggeon component $N_{\mathbb{R}}$, as well as the parameter Q_0 , which is a typically non-perturbative proton scale.

D. Golec-Biernat-Wüsthoff (GBW) saturation model

The saturation model proposed some time ago by Golec-Biernat and Wüsthoff [22,23] was formulated in the color dipole picture. In this formalism both the inclusive and diffractive cross sections may be calculated. The diffractive structure function $F_2^{D(3)}$ is the sum of three contributions [23] :

$$F_2^{D(3)}(Q^2, x_{\mathbb{P}}, \beta) = F_T^{q\bar{q}} + F_L^{q\bar{q}} + F_T^{q\bar{q}g}, \quad (17)$$

The incoming virtual photon γ^* (transversely or longitudinally polarised) which interacts diffractively with the proton forms either the $q\bar{q}$ or $q\bar{q}g$ Fock state. The $F_L^{q\bar{q}}$ and $F_T^{q\bar{q}}$ components dominate in the region of large or intermediate values of β respectively, while the term $F_T^{q\bar{q}g}$ is most important at small β . The longitudinal component $F_L^{q\bar{q}g}$ is the higher twist contribution and therefore may be neglected.

The two terms from Eq. (17) related to $q\bar{q}$ dipoles are given by the following formulae

$$x_{\mathbb{P}} F_{q\bar{q},L}^D(Q^2, \beta, x_{\mathbb{P}}) = \frac{3Q^6}{32\pi^4 \beta B_D} \cdot \sum_f e_f^2 \cdot 2 \int_{z_0}^{1/2} dz z^3 (1-z)^3 \Phi_0, \quad (18)$$

$$x_{\mathbb{P}} F_{q\bar{q},T}^D(Q^2, \beta, x_{\mathbb{P}}) = \frac{3Q^4}{128\pi^4 \beta B_D} \cdot \sum_f e_f^2 \cdot 2 \int_{z_0}^{1/2} dz z (1-z) \{ \bar{Q}^2 [z^2 + (1-z)^2] \Phi_1 + m_f^2 \Phi_0 \}, \quad (19)$$

where the sum runs over all active flavours f , each with charge e_f and mass m_f , and integrate over the light-cone momentum fraction of the virtual photon carried by the quark or antiquark z . The lower limit of the integration is given by $z_0 = (1/2) \left(1 - \sqrt{1 - 4m_f^2/M_X^2} \right)$ where M_X denotes the invariant mass of the diffractive system. The functions $\bar{Q}^2$ and $\Phi_{0,1}$ are defined as

$$\bar{Q}^2 = z(1-z)Q^2 + m_f^2, \quad (20)$$

$$\Phi_{0,1} \equiv \left[\int_0^\infty r dr K_{0,1}(\bar{Q}r) \hat{\sigma}(x_{\mathbb{P}}, r) J_{0,1}(kr) \right]^2, \quad (21)$$

where $\hat{\sigma}(x_{\mathbb{P}}, r)$ is the dipole cross section specific for a given model. In the GBW model it has the form [22]

$$\hat{\sigma}(x, r) = \sigma_0 \left\{ 1 - \exp \left(-r^2 Q_{\text{sat}}^2(x)/4 \right) \right\}, \quad Q_{\text{sat}}^2(x) = \left(\frac{x_0}{x} \right)^\lambda \quad (22)$$

which introduces three parameters : the maximal possible value of the dipole cross section σ_0 and two parameters characterizing the saturation scale $Q_{\text{sat}}^2(x)$ that is λ and x_0 .

The third component in Eq. (17) representing $q\bar{q}g$ state has the form

$$\begin{aligned} x_{\mathbb{P}} F_{q\bar{q}g}^D(Q^2, \beta, x_{\mathbb{P}}) &= \frac{81\beta\alpha_S}{512\pi^5 B_D} \sum_f e_f^2 \int_\beta^1 \frac{dz}{(1-z)^3} \left[\left(1 - \frac{\beta}{z} \right)^2 + \left(\frac{\beta}{z} \right)^2 \right] \\ &\times \int_0^{(1-z)Q^2} dk_t^2 \ln \left(\frac{(1-z)Q^2}{k_t^2} \right) \left[\int_0^\infty u du \sigma_d(u/k_t, x_{x_{\mathbb{P}}}) K_2 \left(\sqrt{\frac{z}{1-z}} u \right) J_2(u) \right]^2. \end{aligned} \quad (23)$$

This formula was obtained in [23] using the two-gluon exchange approximation. In addition, strong ordering of transverse momenta of the quarks and the gluon in the $q\bar{q}g$ dipole was assumed. Notice that (23) is valid only when we consider massless quarks.

Each contribution is proportional to the inverse of diffractive slope B_D for which we take $B_D = 6.0 \text{ GeV}^{-2}$. The $q\bar{q}g$ component is also proportional to the strong coupling α_S . Since this is not clear which value of α_S should be used we made this coupling a parameter in our fits which effectively weights the $q\bar{q}g$ contribution to the diffractive structure function.

In this paper we use the version of the GBW model with three light quarks only. In addition, we assume these quarks to be massless.

III. DATA SETS

In this section, we describe the data used in the following fits. We use the latest t -integrated diffractive cross section measurements from H1 [1] (H1RAP) and ZEUS [3] (ZEUSMX) experiments, derived from the diffractive process $e + p \rightarrow e + X + Y$, where the proton stays either intact or in a low mass state Y . These two data sets are fitted independently and compared.

In case of H1 data [1], measurements are presented in terms of the t -integrated reduced cross section $\sigma_r^{D(3)}(x_{\mathbb{P}}, x, Q^2)$ defined by the relation

$$\frac{d^3 \sigma^{ep \rightarrow eXY}}{dx_{\mathbb{P}} dx dQ^2} = \frac{4\pi\alpha^2}{xQ^4} \left(1 - y + \frac{y^2}{2} \right) \sigma_r^{D(3)}(x_{\mathbb{P}}, x, Q^2)$$

with $\sigma_r^{D(3)} = F_2^{D(3)} - \frac{y^2}{1+(1-y)^2} F_L^{D(3)}$. We notice that the relation $\sigma_r^{D(3)} = F_2^{D(3)}$ is a very good approximation except at large y .

ZEUS data are presented in terms of diffractive cross sections differential in M_X , $d\sigma_{diff}^{*p}/dM_X$, and converted to values for the diffractive structure function values $F_2^{D(3)}$ [3].

Note that these two data sets represent different methods of measurements, and therefore different domain in M_Y , namely $M_Y < 1.6 \text{ GeV}$ in case of H1 and $M_Y < 2.3 \text{ GeV}$ in case of ZEUS. In the following, all cross section measurements are corrected to the domain $M_Y < 1.6 \text{ GeV}$, after multiplying ZEUS values by the global factor 0.85 [1,3].

In addition to the two previous data sets, we use the diffractive cross sections extracted by H1 and ZEUS experiments from the process $e + p \rightarrow e + X + p$, where the leading proton is detected [2,4]. This way of tagging diffractive events is of course very interesting but suffers from a limited detection acceptance, which gives more restricted samples in terms of kinematic coverage. This is why we use them only in global fits with all available data sets. Also, in order to keep the compatibility between all data sets, cross section measurements from the leading proton samples are corrected to the domain $M_Y < 1.6 \text{ GeV}$, by multiplying them with the global factor 1.23 [1] which has been obtained by comparing the H1 data requiring a rapidity gap and the data when the proton is tagged in the final state in roman pot detectors.

To summarize, we give the different data sets used in the fits performed in the following ².

- σ_r^D measured by the H1 collaboration using the rapidity gap method [1] labeled H1RAP, this is the default data set which is not corrected further;
- F_2^D measured by the ZEUS collaboration using the “ M_X method” [3] labeled ZEUSMX, data multiplied by a global factor 0.85. Note that the ZEUS experiment gives directly the values of the structure functions F_2^D , i.e. reduced cross sections corrected from the contribution of F_L^D , and we use these values in the following;
- σ_r^D measured by the H1 collaboration when a proton is detected in roman pot detectors [2] labeled H1TAG, data multiplied by the global factor 1.23;
- F_2^D measured by the ZEUS collaboration when a proton is detected in roman pot detectors [4] labeled ZEUSTAG, data multiplied by the global factor 1.23.

IV. RESULTS USING THE PSF MODEL

Before getting into the results of the QCD fits, let us mention a few technical points how the fits are performed. We do not fit the initial scale Q_0^2 as in Ref. [1], such that we get the best χ^2 value and thus the best fit, with a fixed number of parameters. We have chosen to increase the number of parameters until a fit result stable under a variation of the input scale Q_0^2 is obtained. As a result, the χ^2 value and the shapes of the distributions for quarks and gluons do not depend on the choice of Q_0^2 . We have checked that we obtain very similar results as in Ref. [1] while doing the QCD fit under the same conditions as in Ref. [1] (see appendix A).

As mentioned in the previous section, we consider first the H1 data set alone (H1RAP). Further restrictions on the kinematical plane are requested so that the DGLAP based fits are valid. The two cuts, $M_X > 2$ GeV and $\beta < 0.8$, are necessary to avoid a kinematic range where higher twists effects are expected to be large, which would spoil the quality of the determination of the DPDFs.

To allow the fit to be stable for the H1 rapidity gap data alone (H1RAP), we have to consider 5 parameters for the quarks (see Eq. (3)) and 2 for the gluon (see Eq. (4)). With a similar cut scenario as in Ref. [1], $Q^2 \geq 8.5$ GeV², $M_X > 2$ GeV and $\beta < 0.8$, we obtain a $\chi^2 = 169.3$ for $Q_0^2 = 3$ GeV² and $\chi^2 = 169.8$ for $Q_0^2 = 1.75$ GeV², for 190 data points included into the QCD fit. Only statistical and uncorrelated systematic uncertainties, added in quadrature, are considered in this analysis. We have also varied the values of Q_{min}^2 , and the results are detailed in Appendix B. Following our method, we can produce DPDFs stable within variations of Q_{min}^2 , which is not the case in Ref. [1]. It allows us also to fit all data points with $Q^2 \geq 4.5$ GeV², whereas the cut is taken at 8.5 GeV² in Ref. [1]. In the kinematic domain defined by $Q^2 \geq 4.5$ GeV², $M_X > 2$ GeV and $\beta < 0.8$, we obtain a $\chi^2 = 250.3$ for 240 data points, using $Q_0^2 = 3$ GeV² as the initial scale for DPDFs definition.

A parallel analysis is followed for the ZEUS data set [3] (ZEUSMX), with similar results illustrated on Fig. 15. Note that ZEUS measurements have been multiplied by the global factor 0.85 as explained in section III. The stability of the QCD fit is obtained with 4 parameters for the quarks ($E_S = 0$ in Eq. (3)) and 2 for the gluon. In this case, χ^2 values and shapes are stable within variations of Q_0^2 and no significant dependence of the distributions is observed as a function of Q_{min}^2 . In the kinematic domain defined by $Q^2 \geq 4.5$ GeV², $M_X > 2$ GeV and $\beta < 0.8$, we obtain a $\chi^2 = 100.9$ for 102 points and $Q_0^2 = 3$ GeV², with the parameters given in Table I. For $Q_0^2 = 1.75$ GeV², we get $\chi^2 = 99.9$. Again for this study, only statistical errors are considered in this analysis.

²Note that not all models are able to describe the full data sets since their domain of validity is restricted and these additional cuts will be given while describing the fits

Table I- Pomeron quark and gluon densities parameters for the three different kinds of fits (H1RAP alone, ZEUSMX alone, and all four combined data sets). No Reggeon contribution is necessary for the ZEUSMX data set, as explained in Ref. [3]. Also, the parameter B_S is found to be 0 for this particular fit.

Data set	χ^2 (stat. and syst. error)	Nb. of data points
H1RAP	217.9	240
H1TAG	27.5	57
ZEUSMX	109.5	102
ZEUSTAG	22.7	45

Table II- χ^2 values per data set for the global QCD fit with statistical and systematics errors added in quadrature (see text). The fit parameters are found to be very close if only statistical errors are used during the minimisation procedure.

In a second step, we combine the four data sets defined in section III, with the normalisation factors for each set defined in this previous section. To realise this global fit, we use by default the total errors in the definition of the χ^2 . The kinematic domain is again restricted to $Q^2 \geq Q_{min}^2$, $M_X > 2$ GeV and $\beta < 0.8$, and we study the stability of the results when varying Q_0^2 and Q_{min}^2 (see Appendix B). For $Q_{min}^2 = 4.5$ GeV², we get a χ^2 value of 377.6 for 444 data points, with the values for each data sets given in Table II and parameters listed in Table I³. Note that we assign a global Reggeon normalisation parameter to each data set for which this contribution is needed. However, the parameters for the Reggeon and Pomeron trajectories (defining the flux factors of Eq. (2)) are the same for all data sets, with $\alpha_{\mathbb{P}}(0)$ considered as a free parameter in the fit.

The fit results are displayed in Fig. 2. We show the quark and gluon densities in the Pomeron (DPDFs) for H1 data only (H1RAP), ZEUS data only (ZEUSMX) and all four data combined sets. We note that the Pomeron is gluon dominated for all fits. On the other hand, the shape of the gluon distribution is quite different between the H1 (H1RAP) and ZEUS (ZEUSMX) data sets, where the high z contribution to the gluon density is small for the ZEUS data fit. The fact that the parton distributions for the combined fits are close to the H1 results is simply due to the larger number of H1 data points compared to ZEUS ones. The gluon density at high β is however poorly known and the uncertainty is of the order of 25 %. This high β region is of particular interest for the LHC since it represents for instance a direct background to the search for exclusive events [9]. More data sets are needed to further constrain this region such as diffractive jets production at HERA, or Tevatron diffractive jet cross section measurements.

It is also interesting to show the uncertainty on the high β gluon density in the Pomeron by giving the uncertainty on the parameter ν if the gluon density is multiplied by $(1 - \beta)^\nu$. The value of ν from the fits to the H1RAP and

³We can also perform the QCD fits using the total error for each data set separately, which gives a χ^2 value of 198.7 for 240 data points in the case of H1RAP. When we compare to the global QCD analysis (with χ^2 value of 377.6 for 444 data points), we observe that the χ^2/dof are compatible, which also justifies our approach to combine all data sets.

ZEUSMX data sets respectively is found to be 0 ± 0.05 for a variation of χ^2 of 15 units for the 4 combined data sets, reflecting the large uncertainty on the gluon density at large z .

FIG. 2. Singlet and gluon distributions of the Pomeron as a function of z , the fractional momentum of the Pomeron carried by the struck parton, derived from QCD fits on H1RAP data alone, ZEUSMX data alone or the four data sets together. The parton densities are normalised to represent x_P times the true parton densities multiplied by the flux factor at $x_P = 0.003$.

V. RESULTS USING THE BEKW MODEL

Using formulae of section (II.B.1), we can perform fits of the structure function measurements (or reduced cross sections) over the whole kinematic range, including the highest β or lowest M_X values, as the longitudinal component

of this model behaves as a higher-twist part. In a first step, a fit is performed on H1RAP data alone, with only one selection cut $Q^2 > 4.5 \text{ GeV}^2$: we obtain a $\chi^2 = 286.8$ for 247 data points. Only statistical and uncorrelated systematic uncertainties, added in quadrature, are considered. A parallel analysis is performed for the ZEUSMX data set, with a $\chi^2 = 193.5$ for 142 data points. Parameters are given in Table III for these two fits.

Then, a global fit is performed to the reduced cross sections of all data sets, considering for this analysis the total errors (as in section IV). The parameters are given in Table IV and the values of the χ^2 per data sets are presented in Table IV⁴. Fig. 4 shows the good description of the diffractive structure function measurements (H1RAP and ZEUSMX) by the fit result over the whole kinematic range. Only two data sets are presented on this Fig. 4, namely [1,3], to keep the plot lisible. From this Fig. 4, we observe that, taking into account the term $F_2^{D(3)}(q\bar{q}_L)$, the highest β bin is properly described except for the lowest Q^2 values. We notice also that the prediction for $x_{\text{P}}\sigma_{red}^D$ is decreasing at low x_{P} values for $\beta = 0.9$: it is a reflection of the influence of the longitudinal component, which becomes large in this domain (see section III). If we apply the cuts $M_X \geq 2 \text{ GeV}$ and $\beta \leq 0.8$ to avoid this kinematic domain, the χ^2 for H1RAP improves considerably with a value of 226.6 for 240 data points and for H1TAG, we get a χ^2 of 33.9 for 57 data points. For the other data sets (ZEUSMX and ZEUSTAG) the χ^2/dof is stable. The improvement for H1RAP comes mainly from the kinematic domain $Q^2 \leq 15 \text{ GeV}^2$ and $\beta = 0.9$, which is not well described by the fit.

ZEUSTAG	23.7	45

Table IV- χ^2 values (total errors) per data set for the global BEKW fit (see text).

The resulting value of γ is large (≥ 9), leading to a strong β dependence of the $q\bar{q}g$ term, which is dominant only in the low β region. In this kinematic domain, contributions in which more than two partons emerge from the diffractive hard scattering have also been found to be important in measurements of hadronic final state observables in diffractive DIS [17,18]. The longitudinal $q\bar{q}$ term becomes large for $\beta > 0.5$, indicating a strong higher twist contribution in this kinematic region. At intermediate β , the transverse $q\bar{q}$ term, varying as $\beta(1 - \beta)$ is dominant. These properties are illustrated in Fig. 3 for $x_{\text{P}} = 0.002$. This shows that the scaling violations of diffractive structure functions observed experimentally can be described by the Q^2 dependence of the $q\bar{q}$ term at medium β since the exponent of x_{P} depends on Q^2 .

⁴For this model, we can also perform the BEKW fits using the total error for each data set separately, which gives a χ^2 value of 226.2 for 247 data points in the case of H1RAP. When we compare to the global BEKW analysis (with χ^2 value of 493.1 for 493 data points), we observe, as in the previous section, that the χ^2/dof are compatible.

FIG. 3. The three different contributions of the two-gluon exchange model (BEKW), fitted on all data sets. Results are presented as a function of β , for different Q^2 values, for a fixed $x_{\text{IP}} = 0.002$ value.

FIG. 4. Comparison of H1 (H1RAP) and ZEUS (ZEUSMX) data sets with the prediction of the BEKW global fit. Only the statistical part of the uncertainty is shown for the data points on this plot. A dashed line is drawn for the prediction of the fit on points not included in the analysis.

VI. RESULTS USING THE BP MODEL

In this section, we give the results of the fits based on the dipole model. Using formulae of section (II.B.2), we can perform fits of the structure function measurements in the kinematic domain $4.5 < Q^2 < 120 \text{ GeV}^2$, $M_X \geq 2 \text{ GeV}$ and $\beta \leq 0.8$. First, a fit is performed on H1RAP data alone, we obtain a $\chi^2 = 324.0$ for 175 data points. Only statistical and uncorrelated systematic uncertainties, added in quadrature, are considered. A parallel analysis is followed for the ZEUSMX data set, with a $\chi^2 = 85.8$ for 56 data points. Then, a global fit is performed to all data sets, considering the total errors. Parameters are given in Table V and the χ^2 values per data set are shown in Table VI. Fig. 5 shows the result of the global fit compared to the data sets H1RAP and ZEUSMX. In the kinematic domain under study, the agreement is good but the extrapolation in the highest $\beta = 0.9$ fails to describe the data. We note also that in these fits, the Reggeon component is found to be very low, as the inelastic component is giving a similar behaviour. For the global fit, all Reggeon normalisations are found to be compatible with zero, but for H1RAP, for which we get $N_R = 2.0 \pm 0.5$.

The value of α_P is found to be consistent with the expected intercept for a hard BFKL Pomeron [20]. This intercept is higher than the value obtained from the fit to the structure function F_2 [19]. Q_0 is very close to the value obtained in the proton structure function fit. It should be noted that the scale Q_0 appears in a non-trivial way as the virtuality in the inelastic ($Q/4Q_0$) and the elastic ($Q/2\sqrt{\beta}Q_0$) components. The validity of these results can be checked by starting with two different values of Q_0 for each component and the result of the fit leads to same values within errors, with the same χ^2 . Furthermore, imposing a constant scale for the elastic component, $Q/2\sqrt{\beta}Q_0 \rightarrow Q/Q_0$, leads to a very bad quality fit.

Parameters	H1RAP	ZEUSMX	All data sets

FIG. 5. Comparison of H1 (H1RAP) and ZEUS (ZEUSMX) data sets with the prediction of the BFKL global fit. Only the statistical part of the uncertainty is shown for the data points on this plot. A dashed line is drawn for the prediction of the fit on points not included in the analysis.

VII. RESULTS USING THE GBW SATURATION MODEL

In this section, we give the results of the fits based on the dipole model including saturation effects. Using formulae of section (II.C), we can perform fits of the structure function measurements (or reduced cross sections) over the whole range of β and M_X values, as the longitudinal component of this model behaves as a higher-twist part. Since, as in other models, also in this case the sub-leading Reggeon part is added to the three terms in Eq. (17) the data for all values of x_P are used in the fit.

As shown in [24,25] the GBW saturation model works fairly well when fitted to the inclusive F_2 data only when Q^2 is smaller than 25 GeV². This is because the Q^2 evolution which is expected to be important especially at high values of Q^2 is not present in the GBW model. This evolution introduced in [24] modifies the small r part of the dipole cross section to which the inclusive F_2 at high Q^2 is very sensitive. However the situation for diffractive structure function F_2^D is different since diffraction is sensitive rather to the intermediate r part of the dipole cross section which is essentially the same regardless of the presence or absence of Q^2 evolution. In fact, we have checked that imposing the $Q^2 < 25$ GeV² cut in the fit results in almost no improvement of the fit quality in terms of χ^2 value. Hence, we decided to fit the data using only a $Q^2 > 4.5$ GeV² cut as for other models presented in this paper.

First, a fit is performed on H1RAP data alone, we obtain a $\chi^2 = 272.9$ for 247 data points. Only statistical and uncorrelated systematic uncertainties, added in quadrature, are considered in this analysis. A parallel analysis is followed for the ZEUSMX data set, with a $\chi^2 = 268.0$ for 142 data points. Then, a global fit is performed to all data sets and $\chi^2 = 564.5$ is obtained for 493 data points. Parameters together with χ^2 values per number of data points are given in Table IX. Fig. 6 shows the result of the combined fit together with the H1RAP and ZEUSMX data. A good description is found.

Parameters	H1RAP	ZEUSMX	All data sets
σ_0 [mb]	16.45 ± 0.24	45.83 ± 0.25	27.69 ± 0.14
λ	0.239 ± 0.012	$0.16387 \pm$	$0.199 \pm$
x_0	$6.78 \cdot 10^{-3} \pm 0.43 \cdot 10^{-3}$	$1.59 \cdot 10^{-8} \pm 0.02 \cdot 10^{-8}$	$2.539 \cdot 10^{-5} \pm 0.001 \cdot 10^{-5}$

$N_{IR}(ZEUSTAG)$	-	-	3.46 ± 0.51
$\chi^2/(nb \text{ data points})$	272.9/247	268.0/142	564.5/493

Table IX- Parameters for the GBW fits performed in the range $Q^2 \geq 4.5$ GeV² (see text).

Let us recall that the original GBW parameters from [22] for the fit to F_2 data with three light quarks are $\sigma_0 = 23.03$ mb, $\lambda = 0.288$ and $x_0 = 3.04 \cdot 10^{-4}$. The value of α_s used in [23] was fixed at $\alpha_s = 0.2$. Clearly the parameters obtained here for diffractive fits are substantially different from the original GBW parameters. The λ parameter is smaller than 0.288 regardless of the data set taken to the diffractive fit. The parameter x_0 varies a lot depending on which data we use. However, for the combined fit it is one order of magnitude smaller than found in [22]. This is also reflected in the form of the critical line, which is an important characteristic of the saturation model. This line in (x, Q^2) -plane marks the transition to the domain where the saturation effect are important, *i.e.* to the left of it. In Fig. 7 we show the critical lines determined with the three sets of parameters from Table IX. Only the parameters which characterize the saturation scale, *i.e.* λ and x_0 , are relevant in this case. The original result from [22] is also presented in Fig. 7 for reference. We see that the position of the critical line strongly depends on the data set used in the fit. The line obtained with the combined fit parameters is, however, not far away from the GBW result [22] whereas the line corresponding to ZEUSMX parameters is shifted significantly to the left with respect to other lines.

FIG. 6. Comparison of H1 (H1RAP) and ZEUS (ZEUSMX) data sets with the prediction of the GBW global fit. Only the statistical part of the uncertainty is shown for the data points on this plot. A dashed line is drawn for the prediction of the fit on points not included in the analysis.

FIG. 7. The critical line in the (x, Q^2) -plane obtained with the three sets of parameters given in Table IX. The original GBW result from [23] is shown for reference. The shaded area shows the acceptance region of HERA.

VIII. DISCUSSION

In the previous section, we have seen that all models give a correct description of all data sets. If we compare the χ^2/dof values per data sets in the kinematic range $Q^2 > 4.5 \text{ GeV}^2$, $M_X \geq 2 \text{ GeV}$ and $\beta \leq 0.8$, PSF and BEKW fits are compatible, with a global χ^2/dof of 0.83 and 0.81 (respectively). When we consider in addition the kinematic cut $Q^2 < 120 \text{ GeV}^2$, the BP and GBW approaches lead to a global χ^2/dof of 1.24 and 1.31 (respectively). Then, PSF and BEKW predictions give a better description of the inclusive diffractive measurements but the BP and GBW models are also reasonable and it makes sense to compare some specific features of all models considered above.

Already, some properties have been mentioned in section (IV). For the BEKW parametrisation, we have seen that taking into account the term $F_2^{D(3)}(q\bar{q}_L)$ makes it possible to describe the highest β bin ($\beta = 0.9$), except for the lowest Q^2 values. Then, this model provides a very efficient description of all the inclusive diffractive measurements, with a simple functional form and few parameters. Of course, this is a leading order approach, as the dipole and saturation models we have considered in previous sections. The PSF model is the only one at next-to-leading order, with the other advantage that DPDFs can be used to predict cross sections in hadron-hadron scattering, taking into account also the survival gap probability (see section II.A).

Let us now study the dependence on x_P which is directly related to the rapidity gap dependence. One can define an effective Pomeron intercept in the following way:

$$\alpha_{\mathbb{P}}^{eff} = \frac{1}{2} \left(\frac{d \ln F_2^D}{d \ln 1/x_P} + 1 \right) \quad (24)$$

where the t dependence is integrated out. This effective exponent can also be determined for the inelastic and elastic components separately for the BP model. Results are presented for $\alpha_{\mathbb{P}}^{eff}$ as a function of x_P (Fig. 8) or Q^2 (Fig. 9). In Fig. 8 (b), the effective intercepts of both components from the BP model and their sums have been presented. The range of obtained values sits essentially between these two limits except in the large x_P region ($x_P \geq 10^{-2}$). It is clearly not consistent with the soft Pomeron value (1.08). The shape observed on Fig. 8 (b) can be explained by the large logarithmic corrections induced by the $a^3(x_P)$ term, proportional to $\log^3(1/x_P)$, present in both diffractive components (see formulae 11, 13, 16). The effect of this logarithmic term induces also an x_P dependence of the intercept. Moreover, it can be seen that the x_P dependence of the intercept is different between the elastic and the inelastic components. This induces an apparent breaking of factorisation directly for the diffractive components of this model, which comes in addition to the known factorisation breaking due to secondary trajectories [21]. Fig. 9 shows the Q^2 dependence of the Pomeron intercept $\alpha_{\mathbb{P}}^{eff}$ predicted by all models, with clear differences between the PSF fit and the BEKW model. In the case of PSF model, the Q^2 behaviour is by definition included in the DPDFs and not in the factorised x_P part. In case of BEKW, there is a natural Q^2 dependence arising in the effective Pomeron intercept. A similar shape is observed in the case of the BFKL model, with still a normalisation factor compared to BEKW as discussed above. Note that the significant difference in behaviour between the PSF and the BEKW models is a challenge for experimentalists and the determination of the Q^2 dependence of the Pomeron intercept would provide a good discrimination between models.

Another important conclusion from the previous analysis is the prediction for the longitudinal diffractive structure function by all models. Fig. 10 displays as a function of β the longitudinal component of the proton diffractive structure functions (Fig. 10 (a)) and the ratio R of the longitudinal to the transverse components (Fig. 10 (b)). Here again, we observe significant differences. The BEKW or GBW models predicts only a longitudinal contribution at large β , which behaves in Q^2 as a higher twist part (see section II). On the contrary, the PSF model predicts the leading twist part of F_L^D which is increasing at small values of β and tends to 0 when β tends towards 1. It is interesting to observe that the BP model contains these two features for the behaviour of F_L^D with a leading twist behaviour at low β and a non-zero component for the largest β values.

Also, a striking feature of the diffractive proton structure functions concerns the scaling violation, namely the Q^2 dependence at fixed x_P as a function of β . The structure functions are increasing with Q^2 even at very high β (see Fig. 11 and Fig. 12) at variance with the behaviour of the total proton structure function as a function of x . Note that we have only plotted the Pomeron part of the structure function, then subtracting the Reggeon component from the total structure function prediction. We observe that all models are in good agreement with some small differences in the highest β bin, but much smaller than the experimental uncertainty accessible in this domain.

IX. CONCLUSION AND OUTLOOK

We have discussed the most recent data on the diffractive structure functions from the H1 and ZEUS Collaborations at HERA using four models, based on different approaches of the vacuum exchange structure. We have shown that

the best description of all available measurements can be achieved with either the PSF model or the BEKW model. In the case of the PSF approach, we have derived the DPDFs of the Pomeron under several variations in the analysis. In particular, a global analysis of all available data has been performed with a proper description of these measurements. The main features of the DPDFs, already observed in Ref. [9], are conserved. A large gluon content is still present with a large uncertainty of about 25% at large β . Also, we have shown that the BEKW prediction allows to include the highest β measurements in the analysis. For these values of β , higher twists effects are important and are correctly taken into account by the BEKW model through the longitudinal component of the diffractive cross section. We can mention that this model provides an efficient and compact parametrisation of the diffractive cross section over a large kinematic domain. The BP and GBW models also give a good description of all cross section measurements at small x with a small number of parameters. During the discussion section, we have noticed that the significant difference in behaviour for the effective Pomeron intercept between the PSF and the BEKW approaches is a challenge for experimentalists and the determination of the Q^2 dependence of the $\alpha_{\mathbb{P}}$ would provide a good discrimination between models. Concerning the longitudinal diffractive structure function, we have also observed interesting differences between models. In particular, the BP approach combines the low and high β behaviours of the PSF and BEKW models respectively. Once this observable could be accessed experimentally, it would be of great help for further developments of the theory.

X. ACKNOWLEDGMENTS

We would like to thank E. Perez for fruitful discussions on many aspects of DPDFs. S.S. acknowledges grants of the Polish Ministry of Education and Science: No. 1 P03B 028 28 (2005-08) and N202 048 31/2647 (2006-08) and the French–Polish scientific agreement Polonium.

FIG. 8. Effective Pomeron intercept ($\alpha_{\mathbb{P}} = 0.5(\frac{d \ln F_2^{D(P)}}{d \ln 1/x_{\mathbb{P}}} + 1)$) as a function of $x_{\mathbb{P}}$. The dependence of $\alpha_{\mathbb{P}}$ on $x_{\mathbb{P}}$ is shown for all models at $Q^2 = 30 \text{ GeV}^2$ and $\beta = 0.3$: in plot (a) we present predictions for BEKW as a full line, PSF fit as a dashed line, BP as a dotted line and GBW as a dashed-dotted line. A similar plot (b) is shown for the BP model alone, with elastic and inelastic component drawn separately (dashed and dotted curves respectively).

FIG. 9. Effective Pomeron intercept as a function of Q^2 . The dependence of $\alpha_{\mathbb{P}}$ on Q^2 is shown for all models at $x_{\mathbb{P}} = 10^{-3}$ and $\beta = 0.3$: in plot (a) we present predictions for BEKW as a full line, PSF fit as a dashed line, BP as a dotted line and GBW as a dashed-dotted line. A similar plot (b) is shown for the BP model alone, with elastic and inelastic component drawn separately.

FIG. 10. Predictions for $x_F F_L^D$ and $R^D = \frac{F_L^D}{F_2^D - F_L^D}$ as a function of β at $Q^2 = 30 \text{ GeV}^2$ and $x_F = 10^{-3}$. We present predictions for BEKW as a full line, PSF fit as a dashed line, BP as a dotted line and GBW as a dashed-dotted line.

FIG. 11. Scaling violations, $x_{\text{P}} F_2^{D(\text{IP})}$ as a function of Q^2 at different values of β and $x_{\text{P}} = 10^{-3}$. We present predictions for BEKW as a full line, PSF fit as a dashed line, BP as a dotted line and GBW as a dashed-dotted line.

FIG. 12. Scaling violations, $x_{\mathbb{P}} F_2^{D(\mathbb{P})}$ as a function of Q^2 at different values of β and $x_{\mathbb{P}} = 10^{-3}$. We present the BP model predictions, with elastic and inelastic components shown separately (dashed and dotted curves respectively).

XI. APPENDIX A : REPRODUCING H1 FIT A

In Ref. [1], the normalisations of the flux of Pomeron and Reggeon are defined in a different way, compared to our definitions in this paper or in our previous analysis (see Ref. [9]). In this appendix, to compare results from our fit to those of Ref. [1], we follow the same conventions as in Ref. [1] for the normalisations of the flux factors. Also, we use the Reggeon contribution from Ref. [11] and we perform a QCD fit under the same conditions as fit A of Ref. [1] : results are presented on Table A and are very close. Note also that, in our procedure, we use only the statistical and uncorrelated uncertainties added in quadrature, which gives a χ^2 of 169.9 for 190 data points, whereas, in Ref. [1], the χ^2 definition also includes parameters for all correlated systematics.

parameters	Our fit on H1 data	Table 3 of Ref. [1] (fit A)
Q_0^2	1.75 GeV ²	1.75 GeV ²
Q_{min}^2	8.5 GeV ²	8.5 GeV ²
$\alpha_{\mathbb{P}}$	1.118 ± 0.008	1.118 ± 0.008
A_S	1.10 ± 0.32	1.06 ± 0.32
B_S	2.33 ± 0.35	2.30 ± 0.36
C_S	0.61 ± 0.15	0.57 ± 0.15
A_G	0.13 ± 0.03	0.15 ± 0.03
C_G	-0.92 ± 0.16	-0.95 ± 0.20
N_{IR}	$2.8 \cdot 10^{-3} \pm 0.4 \cdot 10^{-3}$	$1.7 \cdot 10^{-3} \pm 0.4 \cdot 10^{-3}$

Table A- DPDFs parameters (see text).

XII. APPENDIX B : THE DGLAP FITS

In this appendix, we want to give the systematics checks we performed on the DGLAP based QCD fits to the H1 rapidity gap data alone (H1RAP), ZEUS M_X data (ZEUSMX) or the combined data sets:

- We check the dependence of the DPDFs on variations of the starting scale Q_0^2 in Fig. 13 for the H1 data, very small changes are observed while changing the starting scale from 3 to 1.75 GeV². Note that the results on the ZEUS M_X data and on the combined data sets are given in Figs. 15 and 16 and lead to the same conclusion
- We check the fit stability by changing the cut on Q_{min}^2 , the lowest value of Q^2 of data to be included in the fit. The results are given in Figs. 14 (H1RAP), 15 (ZEUSMX) and 16 for the combined data set where we show the results of the fits to the H1 and ZEUS data after applying a cut on Q_{min}^2 of 4.5, 8.5 and 12 GeV². Differences are noticeable at small β but well within the fit uncertainties. No systematic behaviour is observed within Q_{min}^2 variations.
- We check the dependence on the pion structure function by changing it from the Duke Owens parametrisation to the GRV one [10]. The results are given in Fig. 17 for the fits of all data sets and only very small differences are observed between both fits showing the weak dependence of the fit on the precise knowledge of the Reggeon structure function
- We also check the fit stability by doing it with statistical errors only or with statistical and systematics errors added in quadrature. The results are shown in Fig. 18 and show very small differences on the DPDFs between both fits.

FIG. 13. Singlet and gluon distributions of the Pomeron as a function of z , the fractional momentum of the Pomeron carried by the struck parton, derived from QCD fits on H1 data. Results are presented with $Q_0^2 = 3 \text{ GeV}^2$ (full lines) and $Q_0^2 = 1.75 \text{ GeV}^2$ (dashed lines). The parton densities are normalised to represent $x_{\mathbb{P}}$ times the true parton densities multiplied by the flux factor at $x_{\mathbb{P}} = 0.003$.

FIG. 14. Singlet and gluon distributions of the Pomeron as a function of z derived from QCD fits on H1 data. Results are presented with $Q_{min}^2 = 4.5 \text{ GeV}^2$ (full lines), $Q_{min}^2 = 8.5 \text{ GeV}^2$ (dashed lines) and $Q_{min}^2 = 12 \text{ GeV}^2$ (dotted lines).

FIG. 15. Singlet and gluon distributions of the Pomeron as a function of z derived from QCD fits on ZEUS data. Results are presented with $Q_{min}^2 = 4.5 \text{ GeV}^2$ (full lines), $Q_{min}^2 = 8.5 \text{ GeV}^2$ (dashed lines). Distributions obtained from a fit with $Q_0^2 = 1.75 \text{ GeV}^2$ (dotted lines) is also shown.

FIG. 16. Singlet and gluon distributions of the Pomeron as a function of z derived from QCD fits on all H1 and ZEUS data sets. Results are presented with $Q_{min}^2 = 4.5 \text{ GeV}^2$ (full lines), $Q_{min}^2 = 8.5 \text{ GeV}^2$ (dashed lines). Distributions obtained from a fit with $Q_0^2 = 1.75 \text{ GeV}^2$ (dotted lines) are also shown.

FIG. 17. Singlet and gluon distributions of the Pomeron as a function of z derived from QCD fits on all H1 and ZEUS data sets. Results are presented for a QCD fit using the Owens (full lines) or GRV (dashed lines) parametrisations of the Reggeon contribution.

FIG. 18. Singlet and gluon distributions of the Pomeron as a function of z derived from QCD fits on all H1 and ZEUS data sets. Results are presented for fits using the total errors (full lines) or the statistical errors (dashed lines).
